The dataset

I first got the features and labels and set the status column to be the target label. I then transformed the data values so that every data value is between -1 and 1 without loss of ordering. I then instantiated, trained, and tested various models. 80% of the dataset was used for training a model and the remaining 20% of the dataset was used for testing the particular model. I finished off by comparing the accuracy of all of the models.

The most accurate model in predicting whether a person has Parkinson's disease or not was the XGBoost Model at 94.87%. The second most accurate model in predicting whether a person has Parkinson's disease or not was the Random Forest Model at 92.31%. The third most accurate model in predicting whether a person has Parkinson's disease or not was the Decision Tree Model at 89.74%. The least accurate model in predicting whether a person has Parkinson's disease or not was the Logistic Regression at 71.44%
